INTRODUCTION

Ι

Source rock potential and maximum palaeotemperature analysis was carried out on the Conoco-Gulf 2/1-1 Well, drilled offshore Norway. The samples range in age from Tertiary in the first sample at 3,880', through to ?Jurassic at a depth of 13,600'. Initially the ditch cuttings samples were examined in conjunction with the gamma ray, sonic and lithologic logs for the well in order to identify the major lithologies suitable for source rock potential analysis. On the basis of this examination thirty one samples were selected for analysis; of these, twenty nine were for source rock

potential analysis and eighteen were for maximum palaeotemperature analysis. Drilling mud was removed from the samples by washing in water. The

n

Ŋ

LJ

[^

<u>у</u>.

Iј

PI

selected samples were then examined to ensure that they were free of any contamination materials or obviously caved cuttings. Three different

lithologies were encountered mixed together in the samples from the interval 10,000"-10,600'; hand-picked material from these samples was used in the analysis.

ANALYTICAL AND INTERPRETATION METHODS

ANALYTICAL METHODS

a

n

1. Source Rock Potential Analysis

' A

Source rock potential 'is defined as the potential of argillaceous sediments and carbonates to generate sufficient hydrocarbons for migration to produce commercial oilfields. The source rock potential analysis involves the determination of the amount of organic matter present in the samples, and the extraction of the fraction of the samples which is soluble in a solvent mixture. The soluble portion is then analysed by quantitative thin layer chromatography for hydrocarbons and other constituents (see Table). The advantage in using thin layer chromatography is that analysis can be completed on small samples in a short time.

The organic carbon % is determined by a measurement of the CO² content of the samples which is given by changes in thermal conductivity in a Leco carbon analyser (after the removal of carbonate material), The total organic extract 7. is determined by the extraction of the samples (at minus sixty mesh) with a benzene/methanol solvent over a period of twelve hours, followed'by ttie removal of inorganic and particulate contaminants. The extraction ratio % is defined as follows :

> x 100 Total organic extract 7; Organic carbon 7.

The organic extract of the samples comprises hydrocarbons (paraffins and aromatics), resins and asphaltenes. These paraffins, aromatics and resins plus asphaltenes are determined by thin layer chromatography on the cleaned up organic extract. Densitometry is used to measure the TLC fractions. The analytical results are expressed as hydrocarbons ppm, paraffins % in the

- 2 - -

II

hydrocarbons i.e. paraffinicity, and total resins plus asphaltenes '/,. The aromatics 70 in the hydrocarbons is obtained by subtracting the paraffins 7. value from 10070. Further details on the actual analytical procedures are . of a confidential nature.

2. Maximum Palaeotemperature Analysis

Maximum palaeotemperature is defined as the maximum temperature to which the sample has been subjected In its geological history, i.e. it reflects the degree of organic diagenesis or maturity of the sample. The maximum palaeotemperature analysis is based on the fact that when kerogen is heated in nature, for example as a result of increasing depth of burial with sedimentation, stable intermediate compounds are formed which are typical of the maximum temperature attained. In our analytical method, these intermediate compounds are quantified using an electron spin resonance spectrometer. The electron spin resonance measurements are then calibrated against established standards and converted to maximum palaeotemperatures. In the analysis, the kerogen present in the samples is concentrated before the electron spin

resonance work is carried out. The electron spin resonance-kerogen method and the significance of organic maturity has been discussed recently by Pusey (1973),

INTERPRETATION METHODS

tlon is present.

•• <u>Source Rock Potential Analysis</u>

The analytical results are Interpreted by a petroleum geologist and are initially checked for any anomalous data resulting from the presence of nonindigenous hydrocarbons in the samples which was not detected in the sample selection procedure. The main data credibility check is the extraction ratio (%) » and if this ratio is over 50%, then contamination by non-indigenous hydrocarbons is Indicated in the sample. Again, if resins and asphaltenes

are absent or very low in samples where hydrocarbons are detected, contamina-

- 3 -

The principal parameter which establishes a sample as a rock with source rock potential, is the hydrocarbons ppm value. If the sample has a hydrocarbon content of over 350 ppm, it is considered to be a rock with source rock potential. The higher the hydrocarbons ppm value of a sample is, then generally the greater is its potential as a source rock. Samples with a hydrocarbon content below 350 ppm do not have source rock potential. This threshold value of 350 ppm has been established by extensive analysis of source rocks associated with producing fields and petroliferous basins, on a world-wide basis. If a sample has a hydrocarbon value of 300 to 350 ppma, then obviously it is approaching close to source rock potential status and such samples are noted separately. When the total organic extract of a sample is less than 300 ppma (0.037,,), it cannot be regarded, by the above definition, as a rock with source rock potential. Consequently thin layer chromatography is not carried out on samples which show a total organic extract of less than 0.037,. It must be noted that the hydrocarbon threshold

value of 350 ppm is only applicable to our particular analytical procedures.

The most typical source rocks show the following features in their . $\dot{\rm organic}$ extracts :

.. i. An extraction ratio of 10-307»,

I

Π

n [j

jri | |

ן ֿיו ננ

р У **Г**]

[J

Π

IJ

b

18

ŢĴ

r

ii. A paraffin content of the extractable hydrocarbons of over607., and conversely an aromatic content of less than 407=.

iii. A resins plus asphaltenes content of less than about 657».

' These parameters may vary from the above mentioned values in rocks with source rock potential, however this fact does not detract from them having source rock potential. Paraffinicity tends to increase with depth towards the mature end of the zone of potential generation of commercial oil; and there is a corresponding decrease in resins plus asphaltenes values.

There is no cut-off limit on the organic carbon % data, and shales with

•4-

organic carbon contents of less than 1% can be good source rocks. However, if no organic material is present or is very Low (less than 0.037. organic carbon), then the sample cannot have source rock potential. A reasonable organic carbon content in a sample pr-ovides encouraging data with regard to source rock potential, however the determining factor is the hydrocarbons ppm value. -&

2. Maximum Palaeotemperature Analysis

۲۹ ا

Π

[]

f1

LJ

PI

n

7

n

n U An immature sample (one that has not generated sufficient hydrocarbons) has low maximum palaeotemperatures. A mature sample (one that has been hot enough in its history to generate commercial hydrocarbons) has medium maximum palaeotemperatures. They'are indicative of oil potential (i.e. oil, oil and gas zone). Samples which have high maximum palaeotemperatures in excess of 300°F indicate only thermally generated gas potential (i.e. dry gas zone). Pusey (1973) has described examples from southern North America using maximum palaeotemperature analysis.

ANALYTICAL RESULTS AND INTERPRETATION

The results of the source rock potential and maximum palaeotemperature analysis of the thirty one samples are presented in Table 1.

1. Source Rock Potential (Figures 1 and 2)

n

١J

r

Ę

Η

The quality of the source rock potential analytical data is considered to be very good. Examination of Table 1 and Figures 1 and 2 indicates that the analysed samples fall into four main groups:

a. Samples 3 to 17 from the 5,200'-9,940' interval (Tertiary) These samples comprise essentially a soft, olive to light olive-grey
mudstone and shaly mudstone. They are characterised by an organic
carbon content of between 1,487~ and 3.327,, and a hydrocarbon content
of between 130 ppm and 490 ppm.

Of these fifteen samples, numbers 3 to 6 (5,200'-6,520'), 9 to 11 $(7,720'-8,260^1)$, 13 (8,680'-8,740') and 17 (9,940') are considered to be rocks with source rock potential since they show hydrocarbon contents which exceed the 350 ppm value dividing source rocks from non-source rocks (see page 4). These samples have paraffin contents of their extractable hydrocarbons ranging from 457. to 90X and resins plus asphaltenes contents of between $62?_0$ and 87%. Although the resins plus asphaltenes contents of these samples are slightly high, in general the source rock potential parameters compare favourably with those found in typical source rocks (see page 4),

Sample 7 (6,940'-7,000') has a hydrocarbon content of 310 ppm which is very close to the 350 ppm threshold value. The source rock potential parameters are similar to those of the nine potential source rocks.

The remaining five samples have no source rock potential.

in

- 6 -

b. <u>Samples 18 (Upper Cretaceous : 10,000'-10,600' : picked lithologies)</u> and 26 (?Lowgr Cretaceous : 12,220-80')

These two samples, from the top and the base of the chalk, comprise a medium grey shale. They are characterised by an organic carbon content of between 0.567- and 1.13%, and by a hydrocarbon content of between 260 ppm and 510 ppm.

Sample 18 is considered to be a rock with source rock potential since it has a hydrocarbon content exceeding the 350 ppm threshold value. The source rock potential parameters of this sample compare well with similar values from typical source rocks.

Sample 26 has no source rock potential.

c. Samples 19 to 25 from the 10,000'-12,280' interval (Upper Cretaceous)

These samples comprise essentially a very light grey to yellowish grey chalk (probably slightly impure) with traces of light grey shale. Sample 19 (hand picked) comprises a greyish red shale. These samples are characterised by an organic carbon content of between 0.177. and 0.5470 and by a hydrocarbon content of between 40 ppm and 1,100 ppm.

Samples 23 to 25 (11,920'-12,280*) are considered to be rocks with source rock potential since they show hydrocarbon contents exceeding the 350 ppm threshold value. The source rock potential parameters of these samples compare very well with similar values from typical source rocks.

Sample 19 has a hydrocarbon content of 340 ppm which is very close to the 350 ppn threshold value. The source rock potential parameters for this sample are similar to the potential source rock samples 23 to 25.

Samples 20 to 22 have no source rock potential.,

d• Samples 27 to 31 from the 12,880'-13,540' interval (?Lower Cretaceous-Jin: assic)

These five samples comprise a dark grey, calcareous shale. They

- 7 -

arc characterised by an organic carbon content of between 2.427. and 2.957., and by a hydrocarbon content of between 800 ppm and 2,900 ppm. All of these samples are considered to be rocks with source rock

potential since their hydrocarbon contents exceed the 350 ppm threshold value. In general the source rock potential parameters of these samples compare well with those found in typical source rocks.

2. Maximum-Palaeotemperatures-(Figures-3-and 4)

The quality of the maximum palaeotemperature analytical data is considered to be good.

A calculation of the linear regression between all the maximum palaeotemperatures yields a maximum palaeotemperature gradient of 1.4°F per 100 feet, a correlation coefficient of 0.93 and a surface intercept of 116°F (see Figure 3).

The lower limit of the zona. of commercial oil potential generally occurs at a maximum palaeotemperature of 300°F (see page 5). From Figure 3 it can be seen that a maximum palaeotemperature of 300°F is reached at a depth of approximately 13,600'.

3. <u>Conclusions</u>

К

From the present study of the 2/1-1 Well the following main conclusions can be made :

a. • The Tertiary section analysed between 5,200* and 10,000' comprises soft, olive-grey mudstone; rocks with source rock potential occur in the general interval from 5,200'-8,750'.

b. The section from approximately 10,000'-12,300' comprises chalk with minor shale occurrences. Mature source rocks occur in the lower section of the chalk (11,920'-12,300').

c. The section from 12,300 - 13,540 comprises essentially a dark $g^{re}y$ calcareous shale. This section is considered to have good source rock potential but lies close to the lower lir.it of the zone of commercial oil potential.
