CLASTIC SEDIMENTS OF WELL PHILIPS 7/11-1, North Sea (Norway)

INTERVAL 9589'-9678'; PALEOCENE FM.

IL RESPONSABILE DEL SERVIZIO

S. Donato Mit., 19/12/68

Dr. V. Fois

V.F.

Grain size, sedimentary structures and petrography of the available samples were analysed. All these data are summarized on the sediment log (Encl. 1) with porosity and permeability values. Sandstones were subdivided into types according to their grain size following the procedure indicated in the report "Graphic representation of grain size" (R. Passeggi, Sept. 28, 1967). Grain size analyses data are reported on files at the end of this report.

SEDIMENTOLOGY

We examined two cores from 9589' to 9678', which are in the upper part of the reservoir rock. The reservoir is made of sandstone beds a few meters thick interbedded with thin clay layers rich in fine sand. The cleaner sands are in the upper part of the reservoir.

Sandstone beds are mostly massive but the finer sandstones have parallel or wavy laminations. Bioturbation is often present in shaly intervals. Clay fragments are frequent both in sandstone and in clay beds. There are also structures that can be attributed, in spite of the small size of the cores available, to slippings. These indicate a certain sediments instability during the deposition (growing structure ?) (Encl. 1, Photos).

Grain size analyses show that sands never have medians coarser than 200 microns; the coarser grains instead arrive to 2 millimeters. Medium sands were mostly transported as graded suspensions, fractions coarser than 700-800 microns were transported by rolling. Shales interbedded are sandy as we can see from samples n. 44, 62 b, 69 b, 70, 100 ecc. (Encl. 2).

The percentages of lutite (fractions finer than 31 microns) in the sandstones is fairly high and indicate a winnowing effect not very strong.

PETROGRAPHY

Quartz sandstones, light grey, poorly sorted with clay matrix, silica and carbonate cements. Generally carbonate cement is irregularly distributed (Encl. 1). Major components of the detrital fraction are:

- subrounded quartz grains sometimes cataclastic
- scarce, weathered, feldspars, mostly represented by acid plagioclase
- mica flakes in subparallel laminations
- very rare detrital glauconitic grains.

Grain contacts are mostly tangential, sometimes planar.

POROSITY AND PERMEABILITY

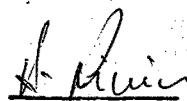

The porosity values in sandstones range between 15 and 25%. Permeability is nearly always between 10 and 100 md (Encl. 1).

This range of porosity is quite high for medium cemented sandstones as they are; this is due to the low percentages of carbonate and silica cements. Permeability instead is not very high in relation to the grain size of the sandstones. In fact these sandstones have a certain percentage of matrix and a poor sorting that keep permeability at relatively low values. Probably silica and carbonate cement have no strong influence on the permeability; pressure solution effect is also negligible as contacts between grains are mostly tangential.

*Mud matrix
Poor sorting*

Enclosure 1 : Sediment log

" 2 : CM, FM, LM, AM diagrams with tables of grain
size analyses data and with tables of core
photos.
